### **Abstract**

This study focuses on the effect of public funding on internal R&D investment and on total innovation intensity on a cross-country comparative level. Using harmonised micro data from 5 different countries, this study analyzes the heterogeneity of the use of policy instruments. Applying a nonparametric matching method to identify the treatment effect, we find that on average firms would have invested significantly less if they would not have received subsidies. On similar grounds, our estimation also takes into account the ?treatment effects on the untreated?. This estimation enables us to assess whether or not governments could further foster R&D activities by extending innovation policies to currently not supported firms. With the exception of one country, all the governments of the sample would benefit from an extension of their subsidy policies. Finally, these two matching results can be combined in order to test for misallocation of public funds. Our analysis does not uncover any systematic misallocation of public funding for the countries under review.

# Evaluation of public R&D policies: A cross-country comparison

This version: April 2011

## Abstract

This study focuses on the effect of public funding on internal R&D investment and on total innovation intensity on a cross-country comparative level. Using harmonised micro data from five different countries, this study analyzes the heterogeneity of the use of policy instruments. Applying a nonparametric matching method to identify the treatment effect, we find that on average firms would have invested significantly less if they would not have received subsidies. On similar grounds, our estimation also takes into account the “treatment effects on the untreated”. This estimation enables us to assess whether or not governments could further foster R&D activities by extending innovation policies to currently not supported firms. With the exception of one country, all the governments of the sample would benefit from an extension of their subsidy policies. Finally, these two matching results can be combined in order to test for misallocation of public funds. Our analysis does not uncover any systematic misallocation of public funding for the countries under review.

# 1 Introduction

Technological change is an important determinant of long-run productivity, essential for securing competitiveness both at the firm-level and at the macro level (Aghion and Howitt, 2005, Jones, 2005). However, investment in R&D suffers from market failure such that the socially optimal investment level is larger than the level of private investment because of external effects (Arrow, 1962). Therefore, many countries subsidize R&D in order to close the gap between private and social equilibrium. Public authorities expect that increasing R&D investment causes intensified technological progress and finally accelerates growth in the long-run. Although R&D subsidy schemes have been evaluated frequently (see David et al., 2000, Klette et al., 2000, Cerulli, 2010), this study will contribute to the existing literature by investigating the effects of R&D subsidies in five countries of different size, different factors of endowments and different innovation policies.

Using harmonized micro data from the 4<sup>th</sup> wave of the Community Innovation Survey (CIS4), covering the years 2002 – 2004 of Belgium<sup>1</sup>, Germany and Luxembourg, as well as a CIS-harmonized survey from South Africa, and Spanish data from the *Panel de Innovación Tecnológica* (PITEC) of the year 2004, allows a large scale study on the effects of innovation policies on total innovation intensity and internal R&D investment in these five countries. As a matter of fact, one would expect that the optimal policy mix varies across countries with different industry structures. Belgium as small open economy possibly applies different innovation policies than South Africa and these countries may put a different emphasis on policy goals. Furthermore, Germany as large economy with strong manufacturing industries, as well as Eastern Germany still regarded as transition economy, certainly requires different policy instruments than Luxembourg with strong focus on financial services.

---

<sup>1</sup> With regard to Belgium, only the Flemish part of the country, Flanders, is included in the following analysis.

Although many aspects of the impact of subsidies on R&D and innovation have been investigated at length in scholarly literature, it remains difficult to draw ultimate conclusions from a bundle of studies that use data from different countries, different data sources, and different methods (see e.g. David et al., 2000). Our study thus has the advantage that we can draw conclusions where possible heterogeneous results are stemming from actual differences across countries and do not result from heterogeneity in the data collection.

A further feature of this study consists in the inclusion of an emerging country, South Africa, and a transition economy (Eastern Germany). Even though recent literature expresses a growing interest in the matter (see e.g. Garcia and Mohnen, 2010, Vertesy and Szirmai, 2010, Ramani and Mukherjee, 2010, Hall and Maffioli, 2008) not many comparable results between industrialized and emerging economies have been obtained so far.

As common in the literature, we are mainly interested in estimating the “treatment effect on the treated”. In other words, we are interested to know how much a firm would have invested if it would not have received subsidies. Thus, we investigate whether public R&D funding stimulates private R&D and innovation activities or whether we face crowding-out effects and firms just substitute public means for private investment. However, an interesting contribution to the literature by this study is that we also analyse the so-called “treatment effect on the untreated”, which is much less commonly done. This effect allows an estimation of what companies that did not receive a subsidy would have invested if they would have gotten support. Finally, the combination of the two estimations allows testing for possible misallocation of public funds as we will outline below.

The remainder of the paper is organized as follows. The second section briefly reviews some recent literature, section three outlines the econometric methods used in the study and

the fourth section introduces the data sources and variables employed in the analysis. Section five presents the empirical results and the final section concludes.

## **2 This study in the context of existing literature**

Over the last years, a great bulk of literature has emphasised the importance of business R&D in fostering innovation, technological change and economic growth (Romer, 1990). Even though the “public good attribute” of knowledge as well as the well known market failures towards R&D investment are valid justifications for governmental intervention, it is crucial for policy-makers to be able to evaluate whether or not their policies achieve the desired effect (i.e. an extension of innovation activities because of public financing and not a mere crowding out of private R&D investment). In this vein, the impact of R&D policies on firms’ innovation behaviour has been of interest in the economic literature for years. David et al. (2000) survey micro and macroeconomic studies on that topic. One major result of their survey is that most of the estimations reviewed are subject to a potential selection bias as recipients for subsidies might be chosen by the government because they are more promising candidates in succeeding their research projects. In this case, funding becomes endogenous to innovative activity, leading to bias in regressions of e.g. R&D intensity on government subsidies. More recent studies addressing the selection bias include Busom (2000), Wallsten (2000), Lach (2002), Czarnitzki and Fier (2002), Almus and Czarnitzki (2003), Duguet (2004), González et al. (2005), Hussinger (2008) and Cerulli and Potí (2008, 2010). Other microeconomic approaches take different output measures into consideration. Examples include the effects of subsidies on patent applications, productivity, fixed-asset investment, returns on sales and growth of sales or employment (see Klette et al. 2000, for a survey). However, no clear cut results come out of these studies and the amount of crowding out, if any, differs from one analysis to another. Indeed, using different estimation methods or

different data, makes it difficult to draw comparable conclusions from these studies. Finally, Cerulli (2010) reviews the principle econometric models used to measure the effects of public support on R&D investment. The author offers a comprehensive overview on the subject by presenting a taxonomy classifying papers according to their estimation methods, the type of data and the type of policy variable.

In this vein, our study focuses on the effect of public funding on firm-level internal R&D investment and on total innovation intensity in a cross-country comparative level.

### *2.1 A cross-country comparison*

Undeniably, the countries included in our analysis are heterogeneous, which makes a policy impact analysis using largely harmonized data interesting. For instance, Belgium is a small, export-oriented economy. In terms of export per capita, Belgium is the world's leading export country. This modern, private-enterprise economy capitalizes on its central geographic location, highly developed transport network, and diversified industrial and commercial base with its main industries concentrated in the Flemish area in the north of the country. Germany, the fifth largest economy in the world (in purchasing power parity terms) and Europe's largest, is a leading exporter of machinery, vehicles, chemicals, and household equipment and benefits from a highly skilled labour force. The Eastern German economy, however, is still in transition after the re-unification in 1990, and firms suffer from a significant productivity deficiency when compared to Western German counterparts (see e.g. Czarnitzki, 2005). As far as Luxembourg is concerned, even though the country's economic take-off was due to the discovery of iron ore around 1850, its economy is nowadays mainly characterised by its prominent international financial centre, ranking eighth among the largest financial centres worldwide and accounting for about 28% of the country's GDP. With regards to Spain, though most of the country's labour force works in the tertiary sector (a bit more than 60%), Spain counts among the biggest car producers on the world market. Besides holding the

biggest fishing fleet of the EU, it is also a large exporter of steel, chemicals and clothing and one of the most important producers of olive oil. Finally, South Africa - a middle-income, emerging market - is the economic powerhouse of Africa. While the country presents modern infrastructure, good communication networks and a stock market ranked 17<sup>th</sup> largest in the world, its economy is above all characterised by its abundant supply of natural resources, leading the continent in industrial output and mineral production.<sup>2</sup>

## *2.2 Innovation across countries: innovating industries, firm size distributions and policy mix*

Besides the more or less well-known stylized facts mentioned above, the countries also differ in their innovation activities and composition of technology policy. This can be shown with innovation survey data that we will also use for the subsequent econometric analysis in this study (see section 4 for a detailed description of the data sources).

For instance, looking at the relative distribution of innovators<sup>3</sup> across countries reveals that Luxembourg is specialized in services when it comes to innovation: 38% of innovators are active in business service industries, 12% of innovating firms are in logistics and communication, and 14% of innovators are in trading industries (see Table A.10 in the annex). This pattern is similar for Flanders. Countries such as Germany (both Western and Eastern Germany) and Spain have a larger innovation base located in manufacturing industries in relative terms. Looking at the firm size distribution, however, reveals that Eastern Germany is still in transition. The share of large innovators with more than 250 employees is smallest among all regions considered here (see Table A.11 in the annex). It

---

<sup>2</sup> The “stylized facts” about the different countries mentioned in this paragraph were obtained from various sources; among others the World Banks’ *World Development Indicators*, CIA’s *World Factbooks* and the OECD’s *Economic Survey* series of our respective countries.

<sup>3</sup> An innovator is a firm that introduced at least one new product to its range of goods in the recent three years, implemented at least one new process in the recent three years, or has ongoing innovation projects in the period under review (see OECD/Eurostat, 2005, for the exact definition).

becomes thus evident that Eastern Germany in the mid-2000s still lacked a larger manufacturing base. In general, Table A.11 shows that the size distribution of innovators is quite heterogeneous across countries.

The countries do not only differ with regard to the firm distribution across sectors and size classes, but also with respect to the policy mix concerning innovation. The public initiatives for supporting research, technology development and innovation are vast. For instance, the PRO INNO EUROPE<sup>4</sup> initiative collects information on different policy measures in European Countries. Policy instruments cover all kinds of activities ranging from direct subsidies for R&D in the business sector, start-up financing, public research infrastructure support, knowledge transfer, human resource policies such as researcher mobility, to technology consulting, innovation prizes, road shows and other instruments supporting innovation culture. Among other initiatives, the PRO INNO website lists current policy instruments. For Belgium, 198 different schemes are listed, Luxembourg maintains 28, Spain 138 and Germany 146. A detailed discussion of the difference in the policy schemes is far beyond the scope of this paper. Note however that there is basically no evidence what a successful policy mix should look like. However, Cincera et al. (2009) point out that different policy mixes can lead to efficient innovation policy.

As an example that countries differ in their policy mix, we present the share of firms funded by national versus European resources in our data in Table 1 below. It becomes clear, for instance, that Eastern Germany is still in transition as innovation subsidies are much more frequent than in Western Germany (42% versus 20% of subsidized innovators). However, Western German innovators more frequently participate in European schemes than Eastern German firms. Interestingly, the share of subsidized innovators is highest in Spain (48%).

---

<sup>4</sup> See <http://www.proinno-europe.eu> for more information.

South Africa has the smallest share of innovators receiving subsidies. This could be an indication for the least developed technology policy landscape among our countries.

Unfortunately, with the data at hand, it is not possible to disentangle both sources of financing for more detailed analyses. Nonetheless, it appears highly interesting to see whether direct subsidies for R&D and innovation have the same effect in countries that are as heterogeneous as the ones under review. The question is to know whether crowding out can be excluded for all the countries, no matter the industry structure and the amount of European funding in the public funding scheme, or whether the conclusions change from one country to the other. For instance, South Africa has relatively little support from both national and international sources. Hence, it is vital to see whether the impact of current subsidies in South Africa differs significantly from the impact public support has in other countries, thus justifying the current relatively low support, or whether similar conclusions can be drawn between all countries. This can serve as an initial step to see if current subsidies achieve the desired goal or whether they should be adapted. Given limited national budgets, it is also of high interest to see whether we face misallocation of public funds.

**Table 1: Share of European funding**

	<b>Subsidized innovators in sample</b>		<b>Innovators receiving European funding</b>	
	absolute number in sample	in %	absolute number in sample	in %
Flanders	237	30%	56	24%
Western Germany	301	20%	112	37%
Eastern Germany	310	42%	77	25%
Spain	2870	48%	585	20%
Luxembourg	73	29%	11	15%
South Africa <sup>1</sup>	63	12%	4	6%

<sup>1</sup>For South Africa, the money comes from a foreign government. However, it is not possible to disentangle international (multilateral) aid (like e.g. financial support coming from the EU or US Aid) from bilateral support stemming from a foreign government's development aid.

### 2.3 *Our study in the context of existing literature*

In this context, the present study complements the existing literature in mainly two aspects:

(1) we analyse the effects of public subsidies in the context of these heterogeneous economies. Compared to most existing studies where no clear-cut comparative results could be found, our estimation presents the advantage of allowing for comparable conclusions. Based on harmonized data, the estimation allows concluding that different findings come from actual differences in the use of public policies (e.g. “picking the winner” vs. “aiding the poor” strategies) and not because of different data collection methods. Even though several comparative studies have already been done in this research area (see e.g. Czarnitzki et al., 2007 comparing Finland and Germany, Aerts and Schmidt, 2008, comparing Flanders and Germany or Wolff and Reinthaler, 2008, using a panel of OECD countries), these studies all focus on developed economies, and, even though they all reject full crowding out effects, it remains difficult to compare the results among the various studies given that different data sources and different estimation methods are used.<sup>5</sup>

(2) Our estimation takes into account the “treatment effects on the untreated”. Not frequently done in the literature so far (see e.g. Gonzalez and Pazo, 2008; or Gonzalez et al., 2005), this estimation enables investigating whether or not governments could further foster R&D activities by extending innovation policies to currently not supported firms in order to accelerate technological progress and long-term growth. What the above studies do not consider though, is the combination of both treatment effects. As a matter of fact, the two matching results, i.e. the treatment effect on the treated and the treatment effect on the untreated, can be combined in order to detect possible misallocations of public resources.

---

<sup>5</sup> An interesting contribution in terms of country comparison has also been made by the OECD (2009) in a comparative study of European and non-European countries. Even though they use a different estimation method from ours as well as different covariates, the results they find on the effects on subsidies on R&D expenditures are in line with our findings (see next section). While one emerging country is included in their analysis (namely Brazil), the study does not cover any African countries. Hence no comparisons with our findings for South Africa can be made.

### 3 Econometric Method

The literature on subsidies has recently emphasized that observed treatments and outcomes may be subject to selection bias. As a matter of fact, subsidies are not attributed randomly, but first firms must chose to participate in a public financing scheme, and second, the beneficiaries will get chosen based on a certain number of selection criteria determined by the funding agency. The literature on the econometrics of evaluation offers different estimation strategies to correct for selection bias (see Heckman et al., 1999, Imbens and Wooldridge, 2009, for surveys). In this paper we apply matching estimators.

Matching directly addresses the question "What would a treated firm with given characteristics have done if it had not been treated?" A treatment in our context is the receipt of innovation subsidies. Those observations on treated firms are compared with a selected group of non-treated firms with similar characteristics (not with all non-recipients). Our fundamental evaluation question can be illustrated by an equation describing the average treatment effect on the treated individuals or firms, respectively:

$$E(\alpha_{TT}) = E(Y^T | S = 1) - E(Y^C | S = 1) \quad (1)$$

where  $Y^T$  is the outcome variable. We will consider various measures of innovation in the subsequent empirical analysis. The status  $S$  refers to the group:  $S=1$  is the treatment group and  $S=0$  the non-treated firms.  $Y^C$  is the potential outcome which would have been realized if the treatment group ( $S=1$ ) had not been treated. The problem is obvious: while the outcome of the treated firms in case of treatment,  $E(Y^T|S=1)$ , is directly observable, it is not the case for the counterpart. This is defined as the basic problem of causal inference (Holland, 1986). What would these firms have realized if they had not received the treatment?  $E(Y^C|S=1)$  is a counterfactual situation which is not observable and, therefore, has to be estimated. In the case of matching, this potential outcome of treated firms is constructed from a control group

of firms that did not receive innovation subsidies. The matching relies on the intuitively attracting idea to balance the sample of program participants and comparable non-participants. Remaining differences in the outcome variable between both groups are then attributed to the treatment.

Initially the counterfactual cannot simply be estimated as average outcome of the non-participants, because  $E(Y^C|S=1) \neq E(Y^C|S=0)$  due to the possible selection bias. The participant group and non-participant group are expected to differ, except in cases of randomly assigned measures in experimental settings. Rubin (1977) introduced the conditional independence assumption (CIA) to overcome the selection problem, that is, participation and potential outcome are independent for individuals with the same set of exogenous characteristics  $X$ . Thus, the critical assumption using the matching approach is whether we can observe the crucial factors determining the entry into the programme. If this assumption is valid, it follows that

$$E(Y^C | S = 1, X) = E(Y^C | S = 0, X) \quad (2)$$

The outcome of the non-participants can be used to estimate the counterfactual outcome of the participants in case of non-participation provided that there are no systematic differences in the observed characteristics between both groups. The treatment effect can be written as

$$E(\alpha_{TT}) = E(Y^T | S = 1, X = x) - E(Y^C | S = 0, X = x) \quad (3)$$

Conditioning on  $X$  takes account of the selection bias due to observable differences between participants and non-participants. In our case, we conduct a Nearest Neighbor matching, that is, for each treated firm we pick the most similar firm from the potential control group of non-subsidized firms. In addition to the CIA, another important precondition

for consistency of the matching estimator is common support, i.e. it is necessary that the control group contains at least one sufficiently similar observation for each treated firm. In practice, the sample to be evaluated is restricted to common support. If the overlap between the samples is too small, the matching estimator is not applicable.

As one often wants to consider more than one matching argument, one has to deal with the "curse of dimensionality". If we employ a lot of variables in the matching function, it will become difficult to find appropriate controls. Rosenbaum and Rubin (1983) suggested to use a propensity score as a single index and thus to reduce the number of variables included in the matching function to just one. Therefore a probit model is estimated on the dummy indicating the receipt of subsidies  $S$ . The estimated propensity scores are subsequently used as matching argument. Lechner (1998) introduced a modification of the propensity score matching ("hybrid matching") as one often wants to include additional variables, e.g. like firm size, directly in the matching function. In this case, instead of a single  $X$  (the propensity score), other important characteristics may be employed in the matching function. The matching protocol in Table 2 summarizes the empirical implementation of the matching procedure used in this paper.

The calculation of the "treatment effect on the untreated" is analogous to the method outlined above. In this case, one searches for twins of the non-subsidized firms in the group of subsidized firms (see e.g. Lechner and Gerfin, 2001, for more details).

**Table 2: The matching protocol**

- 
- Step 1 Specify and estimate a probit model to obtain the propensity scores  $\hat{P}(X)$ .
- Step 2 Restrict the sample to common support: delete all observations on treated firms with probabilities larger than the maximum and smaller than the minimum in the potential control group. (This step is also performed for other covariates that are possibly used in addition to the propensity score as matching arguments.)
- Step 3 Choose one observation from the subsample of treated firms and delete it from that pool.
- Step 4 Calculate the Mahalanobis distance between this firm and all non-subsidized firms in order to find the most similar control observation.  $MD_{ij} = (Z_j - Z_i)' \Omega^{-1} (Z_j - Z_i)$   
where  $\Omega$  is the empirical covariance matrix of the matching arguments based on the sample of potential controls. If only the propensity score is used, there is no need to calculate a multidimensional distance. In that case, e.g. a Euclidian distance is sufficient.
- Step 5 In this application of the matching, we restrict the group of potential neighbors to firms active in the same industry as the particular treated firm. Select the observation with the minimum distance from the remaining sample. (Do not remove the selected controls from the pool of potential controls, so that it can be used again.)
- Step 6 Repeat steps 3 to 5 for all observations on subsidized firms.
- Step 7 Using the matched comparison group, the average effect on the treated can thus be calculated as the mean difference of the matched samples:

$$\hat{\alpha}_{TT} = \frac{1}{n^T} \left( \sum_i Y_i^T - \sum_i \widetilde{Y}_i^c \right)$$

with  $\widetilde{Y}_i^c$  being the counterfactual for  $i$  and  $n^T$  is the sample size (of treated firms).

- Step 8 As we perform sampling with replacement to estimate the counterfactual situation, an ordinary  $t$ -statistic on mean differences is biased, because it does not take the appearance of repeated observations into account. Therefore, we have to correct the standard errors in order to draw conclusions on statistical inference. We follow Lechner (2001) and calculate his estimator for an asymptotic approximation of the standard errors.
- 

## 4 Data and variables

The data used in this paper stem from various sources. The firm level data of Belgium<sup>6</sup>, Germany<sup>7</sup> and Luxembourg come from the Community Innovation Survey (CIS4) and refer to the years 2002 to 2004. The CIS covers most EU member states, Norway and Iceland using a largely harmonized questionnaire throughout participating countries. Eurostat presents

---

<sup>6</sup> The data of Belgium concerns only Flanders, the Flemish part of the country.

<sup>7</sup> For Germany, we split the sample into two parts, Eastern and Western Germany. For the rest of the paper, those two regions will be analyzed and evaluated separately.

detailed descriptive survey results for all countries and aggregate statistics. South Africa, like more and more emerging and developing countries, introduced an innovation survey aligned on the European CIS. This survey is conducted by the Centre for Science, Technology and Innovation Indicators (CeSTII), established to undertake regular national R&D and innovation surveys on behalf of the Department of Science and Technology (DST) and to produce national indicators from the survey results to provide inputs for policy makers and a basis for international comparisons. The CIS databases contain information on a cross-section of firms active in the manufacturing sector and in selected business services.

The data from Spain stem from the *Panel de Innovación Tecnológica* (PITEC). Initiated in 2004 with the aim of improving the availability of statistical information on technological change and innovation activities in Spanish companies, PITEC is the fruit of the joint effort of the National Institute of Statistics (INE), the Spanish Foundation for Science and Technology (FECYT) and the Cotec Foundation<sup>8</sup>.

Our sample concerns only innovative firms and covers manufacturing as well as business related services sectors<sup>9</sup>. Some descriptive statistics concerning industries and firm size can be found in tables A.10 and A.11 in the annex. In total, the sample consists of 9790 observations of 5 different countries, out of which 3854 received R&D subsidies. According to the 3<sup>rd</sup> edition of the Oslo Manual – which is the definition followed by the CIS - an innovative firm is one that has implemented an innovation during the period under review. An innovation is defined as the implementation of a new or significantly improved product (good or service),

---

<sup>8</sup> The data is available online: [http://icono.fecyt.es/contenido.asp?dir=05\)Publi/AA\)panel](http://icono.fecyt.es/contenido.asp?dir=05)Publi/AA)panel).

<sup>9</sup> The core questions of the CIS are the same throughout participating countries. The South African R&D survey also includes these core questions. Even though every country can include national specific questions, the variables used in this study stem from the harmonized part of the core questionnaire. Compared to Luxembourg and South Africa, where the participation in the survey is mandatory for sampled firms, in Belgian and Germany participation is voluntary. With regards to the PITEC, the latter is not an individual survey, but it collects data from different surveys. As such, the core questions of the CIS are also included. As firms face penalties if they do not answer the questionnaires in due time, the response rate is very high.

or process, a new marketing method, or a new organizational method in business practices, workplace organization or external relations (see Eurostat and OECD, 2005).

The receipt of subsidies is denoted by a dummy variable equal to one for firms that received public R&D funding over the period 2002 to 2004 and zero otherwise. No difference is made between the various subsidy programmes. They include national R&D subsidies from the governments of the respective countries of our sample as well as EU financing schemes. As this variable covers a three year period for the countries for which we use CIS4 data, we use values of 2002 for the covariates in order to avoid endogeneity problems. For Spain, we use lagged values of the covariates measured before 2004 whenever possible for the same reason.

As outcome variables, we consider the total innovation intensity, *INNOV\_INT*, at the firm level in 2004, which is the ratio of total innovation expenditure to sales (multiplied by 100), as well as the internal R&D investment, *INT\_RD\_INT*, being the ratio of internal R&D expenditures to sales (multiplied by 100)<sup>10</sup>.

We use several control variables in our analysis that might have an impact on whether or not a firm receives public subsidies. The log of the firm's age (*LNAGE*) is included in the analysis as it is often claimed that older firms are more reluctant to pursue innovation and as a consequence they might be less likely to apply for public research subsidies. The log of the number of employees (*LOGEMP*) takes into account possible size effects. As mentioned before, in order to avoid the concern of potential endogeneity due to the correlation of the receipt of subsidies and increasing the number of employees, we use the number of employment of 2002 and R&D and innovation expenditure of 2004.

Further we include a dummy variable to capture whether a firm is part of a group (*GP*), and if so, whether or not its headquarters are on national or foreign territory (*FOREIGN*).

---

<sup>10</sup> The CIS definition of R&D expenditure follows the Frascati Manual (OECD, 1993).

Firms that belong to a group with the parent company on national territory might be more likely to receive subsidies because they presumably have better information about governmental programmes due to their network linkages. In their decision making process, governments might favour firms that are part of a group because of potential spillover effects and specialised know-how national entities might have from their foreign branches. However, firms belonging to groups with a foreign parent company might be more likely to file applications in their home country. In addition, governments typically maintain special policy instruments for small and medium-sized firms. If a small firm, however, is majority-owned by a large parent company, it would no longer qualify for most SME-programs and hence the likelihood to receive a subsidy is reduced. The dummies *GP* and *FOREIGN* thus also control for this type of company profile, and a-priori it is unclear whether the effect is positive or negative because of the two opposing arguments outlined above.

Usually it is desirable to control for the capital intensity of firms in order to control for different technologies used in the production process. As a matter of fact, companies with capital-intensive production might rely more heavily on innovation activities than labour-intensive firms. Furthermore, capital may serve as collateral in credit negotiations with potential lenders, facilitating access to external sources of financing. Such firms are thus more likely to already have more experience in conducting R&D and innovation activities than firms that faced financial constraints in the past. Unfortunately, we do not have information about firms' capital stock for most countries. However, we can use lagged investment into tangible assets as a proxy variable. We define *KINT* as the ratio of investment into tangible assets divided by the number of employees. For South Africa, we do not have any information, and thus cannot account for this variable. For Flanders, there are many missing values for the investment variable. Instead of imputing these missing values with the help of a mean or of information of other years, we created a dummy variable ( $d(kint = missing)$ ) that

takes on the value 1 if the value for the investment is missing. Once we include this dummy in the analysis, we can impute, for instance, a zero for the missing in the investment variable and the dummy will capture the bias arising from this transformation in the estimated slope of the investment variable.

To control for technological prowess or previous R&D experience, the analysis includes a dummy variable indicating whether firms have permanent, internal R&D activities (*PERM\_RD\_INT*). Finally, we include an export dummy (*EXPORT*) to capture whether a firm faces foreign competition. Such firms may be more innovative and more likely to apply for subsidies as they may have more competition than firms only serving the domestic market. Unfortunately, not all of the control variables described here above were available to the same extent for all the countries under review. Hence, some of the covariates differ from one country to the other. However, as explained in the methodology section, the matching procedure crucially relies on the conditional independence assumption. Thus, we included covariates of interest even if they were not equally available for all the countries. Table 2 shows the descriptive statistics of the variables of our sample.

[Insert Table 3, descriptive statistics, about here]

As the t-tests show, there are some significant differences between the subsidized and the non-subsidized firms. For all the countries but Eastern Germany, the subsidized firms are larger than the non-subsidized ones. With the exception of Luxembourg and Eastern Germany, subsidized firms tend to be more capital-intensive. For Flanders and Germany (East as well as West), we can observe a significant difference in export activities between the treated and the untreated groups. More importantly, in all the countries of our sample, the subsidized firms have significantly more permanent internal R&D activities than the non-

subsidized firms as well as – with the exception of Luxembourg - higher total innovation and internal R&D expenditure. We thus can suspect that governments adopt a “picking-the-winner” strategy, favouring the firms that invest more substantially in R&D and innovation and look thus like more promising candidates than others. Luxembourg appears to be an exception, given that on average internal R&D expenditures and total innovation intensity are not significantly different among the two groups of firms. With the exception of Eastern Germany, the age of the firm does not seem to differ between treated and non-treated groups. Finally, being part of a group or having the parent company abroad does not significantly differ between the subsidized and the non-subsidized firms (except for the group variable in Spain).

## 5 Econometric Results

Before applying the matching methodology, we present the probit models on the likelihood to receive subsidies. These models are used to obtain the propensity score which is employed as matching argument subsequently. The results of the probit estimations on the receipt of subsidies are presented in table 3. As already indicated by the descriptive statistics, size, export, capital intensity and permanent internal R&D are the most important variables driving the selection in most countries.<sup>11</sup> The estimation additionally shows that for the countries where this variable is significant (Flanders and Spain), a firm with a foreign parent company

---

<sup>11</sup> At this stage, it has to be noted that the employment variable for Spain cannot be interpreted in the same straightforward way as for the other countries of the sample. For reasons of opportunity and viability, PITEC started with two samples with data from 2003: a sample of firms with 200 or more employees (sample of big firms (MEG), which represented 73% of all firms with 200 or more employees according to data from the DIRCE), and a sample of firms with intramural R&D expenditures (MID). Given the improvements made by the INE in information on firms undertaking R&D activities, there were enlargements of the second sample in 2004 and 2005. Moreover, in 2004, a sample of firms with fewer than 200 employees, external R&D expenditure and no intramural R&D expenditure (MIDE); and a representative sample of firms with fewer than 200 employees and no innovation expenditure (MEP) were included. For further detail, see [http://icono.fecyt.es/05\)Publi/AA\)panel/bdPITEC\\_June2010\\_ing.pdf](http://icono.fecyt.es/05)Publi/AA)panel/bdPITEC_June2010_ing.pdf).

is less likely to receive subsidies than other firms. The same is true for Spanish firms that are part of a group.

[Insert Table 4, Probit estimations, about here]

Table 4 presents the results of the matching by propensity score.<sup>12</sup> As the means and corresponding t-tests show, our sample is well balanced according to all employed covariates after the matching. There are no statistically significant differences in the exogenous variables. However, with regards to the outcome variables, significant mean differences exist after the matching. Those can be attributed to the treatment and full crowding-out with regard to public funding can hence be rejected. As a consequence, on average, the subsidised firms would have invested significantly less in R&D and innovation if they would not have been subsidized. These findings are in line with the results of previous studies. As a matter of illustration, Almus and Czarnitzki (2003) find that Eastern German firms which received public subsidies increased their innovation activities by about four percentage points. Czarnitzki and Hussinger (2004), evaluating the effect of public R&D funding on R&D intensity and patent outcome for Germany also find that subsidies have a positive effect on their outcome variables. Duguet (2004), focusing on growth of the ratio of firms' R&D to sales for France finds similar results, as well as Czarnitzki and Aerts (2004) focusing on patent outcome for Flanders. All those studies exclude total crowding out.

The fact that after the matching significant mean difference exists between the treated and the non treated group in Luxembourg (and that this difference was not significant before the matching) might indicate that the Luxembourgish government follows an "aiding-the-poor"

---

<sup>12</sup> In two cases, the propensity score matching did not balance the samples in all covariates. Therefore, we applied hybrid matching by including additional arguments in the matching function (see Lechner, 1998). For Western Germany, the matching has been done by propensity score and *LNAGE*. For Flanders, it has been done by propensity score, *FOREIGN* and 2 industry dummies.

strategy rather than a “picking-the-winner” one. However, it could also signify that the government privileges national over foreign firms, as indicated by the negative sign of the *FOREIGN* variable in the probit regression<sup>13</sup>, or, as explained in the previous section, that foreign owned companies tend to apply at their home country more frequently for grants. The fact that the outcome variables are significant at a 5% level for Luxembourg (compared to a 1% significance of most other countries), could be due to the limited size of public support at the firm level, as stipulated by the OECD. The same comment could be applicable for South Africa. Tables A.8 and A.9 in the appendix display OLS regressions for internal R&D intensity and total innovation intensity. One can see that the OLS estimates are comparatively similar to the matching in this case.

[Insert Table 5, matching results: treatment on the treated, about here]

Table 5 displays the results of the treatment effects on the untreated. As for the matching results on the treated, the means and t-statistics of the matching on the untreated show that all the covariates of our sample are well balanced after the matching. As for the outcome variables, significant mean differences exist after the matching (with the exception of South Africa). Those differences can be attributed to a lack of treatment. In other words, with the exception of South Africa, all the countries of the sample would possibly benefit from an extension of their subsidy policies, as by obtaining public funding the non-treated firms would significantly increase both, internal R&D expenditure as well as total innovation intensity (though the former only at the 10% significance level for Flanders).

[Insert Table 6, matching results: treatment on the untreated, about here]

---

<sup>13</sup> The non-significance of this variable in the Probit regression might be attributable to the relatively small size of the sample.

The two matching results, i.e. the treatment on the treated and the treatment on the untreated, can now be combined in order to test for misallocation of public funds. Table 6 presents the estimated treatment effects and the Lechner-corrected standard errors. This information is used to compute a t-test on mean difference. Misallocation of public funds would be found if the treatment effect of the untreated is significantly larger than the treatment effect on the treated. As the results show, the analysis does not uncover any systematic misallocation of public funding in this case. Although some treatment effects on the untreated are larger than the estimated treatment effects on the treated, e.g. in Luxembourg, no difference is significantly different from zero. While this result is reassuring with respect to current policy practice, it appears that more research should be done on possible misallocation. First, our analysis is limited in covariates, and more detailed data would be desirable as more precise matching estimations could be conducted. Second, the insignificance of t-tests in the misallocation exercise also suggests that the governments are not necessarily following a successful picking-the-winner strategy, as the treatment effects on the treated are not significantly larger than the treatment on the untreated. Only for Spain, we find some weak evidence at the 10% level that the treated did actually invest more compared to the situation where other firms would have been funded.

[Insert Table 7, testing for misallocation of public funds, about here]

## **6 Conclusions**

In this paper, we conduct a treatment effects study on harmonized data from five different countries, or six different regions, respectively, as Eastern and Western Germany are analyzed

separately. In line with recent literature on the effects of public R&D or innovation subsidies, we find that full crowding out effects can be rejected. A novel feature of this study is that the data allow concluding that possible heterogeneity in results stem from actual differences in the policy use across different economies, as the data sources are based on largely harmonized innovation surveys from different countries.

A further attribute of the study is the analysis of the treatment effect on the untreated, where we find evidence that untreated firms would actually have benefitted from receiving subsidies. Indeed, we estimate that such firms would have invested significantly more in case of a treatment.

Finally, we also introduce calculations of possible misallocation of public innovation subsidies to this strand of literature. However, with the data at hand, we do neither find a misallocation nor a superiority of the actual policy decision, as the actual treated firms do not invest significantly more than the non-treated firms would have invested if they had received a subsidy. Even though no clear cut recommendations can be drawn from the misallocation exercise, the fact that no crowding out is found shows that the governments' goal of increasing R&D and innovation is fulfilled. Whether it could be further improved constitutes an interesting topic for future research, applying the current misallocation exercise to more detailed data.

Of course, it has to be noted that our study is not without limitations. Although we benefit from harmonized data from different countries, this comes not without a price when compared to other existing studies. First, our nearest-neighbor matching exercise controls only for selection on observables and uses less covariates than other studies cited in this paper that only used data from one country but had more detailed information on the firms in the sample. Second, we cannot control for fixed firm effects as we have to rely on a single cross-section. The availability of panel data would be desirable. If one could control for fixed effects by

using a (conditional) difference-in-difference estimator, for instance, the concern of having only few covariates would certainly be much reduced. Finally, let us note that we attempted to overcome the limitation with respect to selection on observables by applying parametric treatment models that allow controlling for selection on unobservables. However, the available data did not contain a convincing exclusion restriction, i.e. a variable that influences the probability of subsidy receipt, but not the outcome variables. Therefore, we refrained from discussing these results in more detail as the treatment effects identification is poor in these models with the given data. Consequently, we were not able to apply instrumental variable techniques either, which would also offer an approach to deal with selection on unobservables.
